

I. Introduction

Among different approaches to bias correct climate model (CM) results, distribution mapping has been identified as the most efficient one in reproducing the statistics of rainfall at a regional level, and hydrologically relevant temporal scales (e.g. daily). However:

- Non-parametric (empirical) distribution mapping is sensitive to sample length variations, the presence of outliers, and may lead to significant biases, especially in extreme rainfall estimation.
- Bias-corrected results are constrained by the nominal resolution of the RCM used (i.e. ~ 25 km), which does not suffice to accurately resolve the statistical structure of rainfall at a basin level.

Here (see also Mamalakis et al., 2017) we propose a two step parametric approach that addresses the aforementioned two issues:

- a two-component theoretical distribution model (i.e. ✓ Fit Exponential (Exp.) and Generalized Pareto (GP)) to the historical and CM rainfall series \implies *robustness in extreme rainfall modeling*
- ✓ Interpolate the distribution parameters over a user-defined high-

2. Region of study – Available Data

We compare the proposed parametric method with its non-parametric variant, in bias correcting daily rainfall products from 4 CMs (i.e. KNMI, MPI, C4I, SMHE), over Sardinia (Italy) for the period 1951-2008.

Figure 1: a) The island of Sardinia in Italy. Points indicate rainfall stations, while circles indicate the stations used in Figure 2: #110 (blue) and #288 (red). b) Highresolution grid (i.e. 1 km resolution; red dots) and CM grid (25 km resolution; blue circles).

3. Fitting the two-component distribution model

Use a **GP** model for rainfall intensities above a specified threshold u^* , and an **exponential** model for lower rainrates.

Distribution fitting using Least Squares (LS) to account for all available information on low rainrates.

Data used: 243 stations with more than 30 years of recordings

A parametric approach for simultaneous bias correction and high-resolution downscaling of climate model rainfall for practical applications

Figure 2: Empirical (circles) and theoretical (solid lines) complementary CDFs for the selected stations shown in Figure 1.a, in the control period 1951-1965.

Figure 3: Contour maps for the parameters of the two-component distribution model in the control period 1951-1965, interpolated using KUD: a) GP shape parameter ξ (-), b) standardized to zero threshold scale parameter a_0 (mm/d), c) empirically estimated fraction of wet days $p_0(-)$, d) theoretically calculated $p_0(i.e.)$ honoring continuity condition; see Figure 2).

4. Kriging of distribution parameters

5. Simultaneous bias correction and downscaling

$$\boldsymbol{x}_{\text{cor}}^{(m,l)}(t) = \begin{cases} Q_{\text{KUD},l}^{-1} \{ Q_{m,k} [\boldsymbol{x}_{\text{CM}}^{(m,k)}(t)] \} , \ \boldsymbol{x}_{\text{CM}}^{(m,k)}(t) > 0 \\ \\ Q_{\text{KUD},l}^{-1}(p_k) , \ \boldsymbol{x}_{\text{CM}}^{(m,k)}(t) \leq 0 \end{cases}$$

 $x_{CM}(t)$ denotes the rainfall estimate at grid cell k (blue circles in Figure 1.b) on day t from CM m; $x_{cor}(t)$ is the corresponding bias corrected and downscaled rainfall product at location l (red dots in Figure 1.b); Q is the two-component distribution model, and p_k is uniformly distributed in the interval $[0, Q_{mk}(0)]$.

6. KNMI results (control period 1951-1965)

7. Sensitivity to control-validation periods and CM used

$$DRMSE = \left(\frac{1}{N} \sum_{i=1}^{N} \left(\frac{z_i' - z_i}{z_i}\right)^2\right)^1$$

1/2 z_i and z_i are the historical and model-based estimates of statistic Z, respectively.

Table 1: Dimensionless RMSEs (%) for different combinations of controlvalidation periods, based on Q-Q corrected KNMI rainfall products using nonparametric (i.e. empirical; emp.) and parametric (par.) distribution mapping; **bold** values indicate cases where the non-parametric approach performs better.

control period	validation period	mean annual depth		T = 2 years		T = 5 years		T = 10 years		T = 30 years

tindings when

 \checkmark upscaling the results of the parametric approach to the CM grid

randomly eliminating half of the stations

parametric approach performs better, especially for extreme rainfall

Figure 6: Difference $\delta = DRMSE_n - DRMSE_n$ for the statistics in Table 1, obtained by applying the non-parametric bias correction approach (DRMSE_n) and parametric distribution mapping (DRMSE_n) to 4 different CMs, for 3 combinations of non-overlapping control and validation periods. Positive values of δ indicate superiority of the parametric approach.

8. Conclusions

While parametric bias correction of climate model results cannot eliminate the signature of pronounced biases in raw CM rainfall products:

- It demonstrates significant skill in modeling the effects of topography and local climatology on the magnitude, general tendencies, and high-resolution spatial structure of rainfall statistics, including rainfall extremes
- It is rather **insensitive** to the characteristics of the calibration period, including its length, and the climate model used.
