

Application of non-parametric trend analysis to concentration time series data

Artúr Köhler, kohler@ftr2000.hu

1- Data

Groundwater contamination often proves to be a persistent feature of the affected groundwater regime. Persistent plumes regularly monitored. Concentration data gained by repeated sampling of monitoring wells and laboratory analyses of the samples. Concentration data are ordered into time series. Plume behaviour is assessed by concentration trend evaluation. Data of a 14-year-long monitoring of a halogenated aliphatic hydrocarbon plume is used -Nondetect values replaced by 65% value of detection limit¹

2- Trend evaluation

Trends are evaluated using either parametric (like linear regression using least squares) or non-parametric methods. Mann-Kendall statistic is one of the most widely used non-parametric method. Mann-Kendall statistics is generated comparing the data in the time series to each other, as follows:

3- Mann-Kendall test

n = number of data in time serie
 j, k denotes the j th and the k th member of the serie
 $j = 2, 3 \dots n, \quad k = 1, 2 \dots n - 1$

for all $j > k$:

$$\begin{aligned} \text{sign} &= 1 \text{ if } x_j - x_k > 0 \\ \text{sign} &= -1 \text{ if } x_j - x_k < 0 \\ \text{sign} &= 0 \text{ if } x_j - x_k = 0 \end{aligned} \quad S = \sum \text{sign}(x_j - x_k)$$

Significance of S is determined using Z' statistic. $\text{Var}(S)$ is calculated, and corrected for tied groups

$$\text{VAR}(S) = \frac{1}{18} \left[n(n-1)(2n-5) - \sum t_p(t_p-1)(2t_p+5) \right]$$

Where t_p is the number of data in a tied group (i.e. a group of equal values)

$$Z = \frac{S-1}{\sqrt{\text{VAR}(S)}} \text{ if } S > 0; \quad Z = \frac{S+1}{\sqrt{\text{VAR}(S)}} \text{ if } S < 0; \quad Z = 0 \text{ if } S = 0$$

4- Method

-Concentrations reported by a laboratory are not deterministic numbers. They represent a range, specified by laboratory-given measurement precision. This is usually a \pm percentage of the reported concentration

-a 10% precision means that the reported concentration is within a $\pm 10\%$ percentage range of the reported concentration

Laboratory reported concentrations are considered equal, if their $\pm 10\%$ ranges overlap.

If laboratory reported concentrations

$$C_{LR1} < C_{LR2}$$

Then if

$$C_{LR1} \times 1,1 > C_{LR2} \times 0,9$$

Then

$$C_{LR1} \sim C_{LR2}$$

-Comparing reported concentrations with or without the precision range may result in different S statistic, and Z statistic, for two reasons

- S will be directly different because the comparison differences

- $\text{Var}(S)$ will be different because of the difference in tied groups

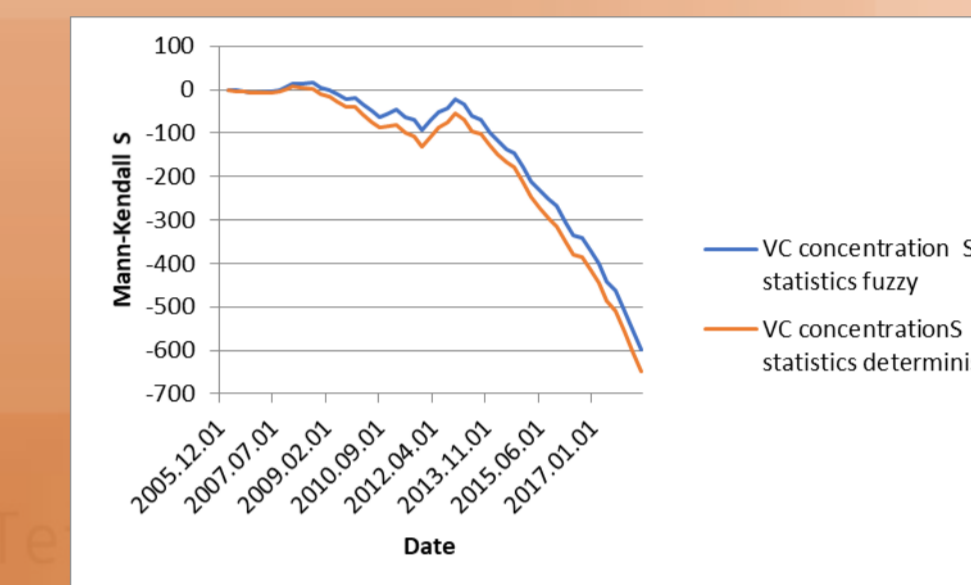

Therefore significance may be different with results in differences in trend perceptions

The two different approach are named here in this presentation „deterministic“ and „fuzzy“

5- Results (examples)

The reason for differences in „S“ is obvious, a deterministicly different concentrations will be equal concentrations as fuzzy

Identical colors indicate tied groups. Depending on the comparison base (i.e. the last data in the time serie) the number and the content of earlier established tied groups may change

While tied groups, once established in the deterministic approach will persist and their influence is stable or increasing with increasing „n“, the fuzzy approach can produce a smaller correction for larger „n“

6- Conclusions

6.1 Fuzzy approach will results in larger correction terms in VAR (S) calculations, however this will not necessarily reflected in „Z“ statistic

6.2 There is no obvious reason, why Mann-Kendall trend analysis produces different trends for certain time series using deterministic and fuzzy approach

6.3 Deviation of fuzzy „S“ can be both direction from deterministic „S“ (regarding zero „S“ as an absolut no trend), therefore using the fuzzy approach has not necessarily dampening effect.

6.4 Time series data structure needs to be looked into to explain the fuzzy „S“ and „Z“ behaviour
