## Abstract 1/3

The Weather Research and Forecasting (WRF) model fitted with the Fitch et al. (2012) scheme for parameterization of the effect of wind energy extraction was used to study the effects of very large offshore wind farms on regional weather. Two real data cases have been run in a high spatial resolution (grid size 500m). Both cases are characterized by a convective flow. The inner model domain covers the North Sea and Denmark. The largest offshore wind farm consists of 202,500 wind turbines each with a capacity of 8MW. The remaining wind farm configurations are 50,176 and 12,544 wind turbines, all covering the same area in the North Sea, due to horizontal spacing changes between individual wind turbines. The model was run for up to 14 hours with and without the wind farm. The impact on the regional weather of these very large wind farms were studied and presented. Furthermore, the effect of horizontal spacing between wind turbines was investigated. Significant impact on the regional weather from the very large wind farms was found. Horizontal wind speed changes occurred up to 3500m above the surface.

## Abstract 2/3

The precipitation pattern was greatly affected by the very large wind farms due to the enhanced mixing in the boundary layer. Increased precipitation occurs at the upstream area within the wind farm, thus leaving the airmass relatively dry downstream when reaching the Danish coast, resulting in a decrease in precipitation compared to the control run. The formation of a low level jet was found above the downstream area of the very large wind farm. Furthermore, wake effects from individual wind turbines decrease the total power production. The wind speed in the simulated cases were above the speed of maximum power production of the wind turbines. Yet most of the 202,500 wind turbines were producing only 1MW due the wake effects. The wind farm with 50,176 wind turbines was found to produce a similar amount of power as the 202,500 configuration.

## Abstract 3/3

Finally, the wind farm consisting of 12,544 wind turbines produced at maximum power through most of the simulations. Therefore, horizontal spacing of 2000m between wind turbines are optimal for minimal wake effect. Through the 14 hour simulations of the wind farm, consisting of 202,500 wind turbines, the maximum achieved  $\text{W/m}^2$  was 10.42 and maximum CF was 32.6%. For the 50,176 wind farm these values were 6.58  $\text{W/m}^2$  and CF 82.3%. Finally, the wind farm consisting of 12,544 wind turbines achieved a peak of 1.99  $\text{W/m}^2$  and a CF of 99.5%.

# Wind turbine used: Vestas V164-8

# Conclusion

- The atmospheric flow reacts to very large wind farms in a similar way to a mountain. (Foehn wind)
- Horizontal spacing should be above 1000m for the V164-8
- $4.000.000 \text{ km}^2$  is required for setup 3 in order to cover entire EU energy consumption
- $1.000.000 \text{ km}^2$  is required for setup 2 in order to cover entire EU energy consumption
- Changes in wave heights and wind driven ocean circulation
- Issues for ship traffic
