Particle method for subsidence estimation

A question of performance

Monte Carlo method (step 1)

$p(x): \{x_i, i=1, \dots, N_e\}$ $p(x^f): \{x_i^f, i=1, \dots, N_e\}$

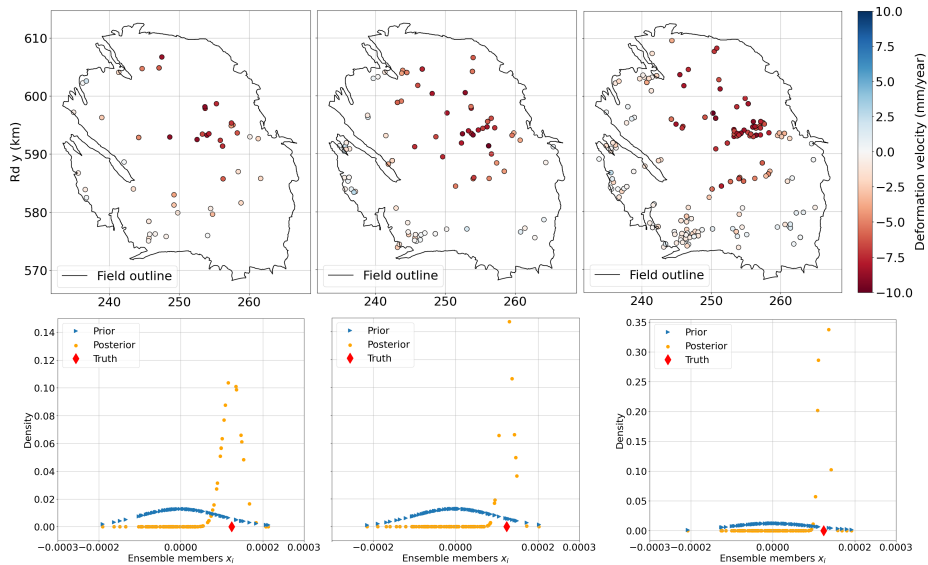

1 Probabilistic method: Monte Carlo

- Prior knowledge on model parameters, $p(x)$
- Ensemble size = number of realizations N_e
- Prior distribution of model prediction, $p(x^f)$

2 Assimilate data, y

3 Create a **posterior weighted distribution** $p(x|y)$

Posterior $p(x|y)$ = "How each realization x_i gives a model prediction close to the observations"

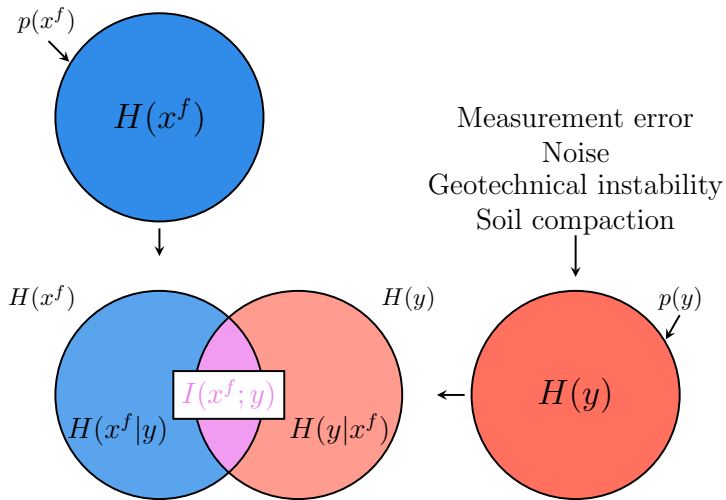

The particle method performance depends on the quality of the posterior \rightarrow Ensemble size.

Entropy

Quantifying the information introduced in the system

- H is the uncertainty (reciprocally the information) on a variable: deformation velocity, y
- "Can we know what signal is contained in the observations?"
- Assimilate this information to estimate model parameters, x

Reduction of the number of observations

Step 1: entropy in InSAR dataset

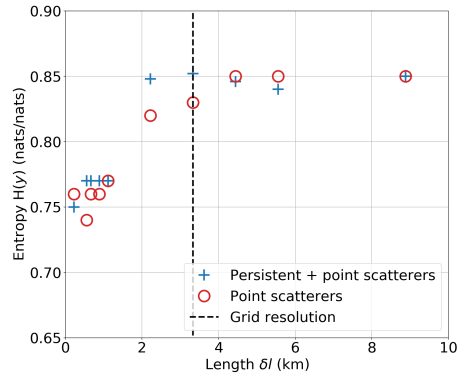

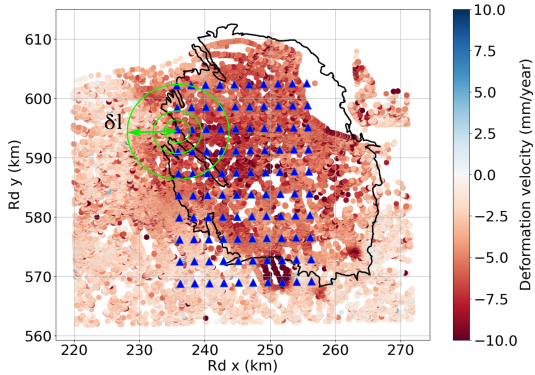

Distributed scatterers: averaged points

Point scatterers: 1 single measurement

	Full dataset (Distributed + point scatterers)	Reduced dataset (Point scatterers)
Dimension	1.5M	662 965
Entropy $H(y)$	0.48	0.49

Step 2: averaging and spatial correlation (100 observations $\rightarrow N_e = 10^6$)

Redundancy is characterized by an increasing entropy: convergence to a Gaussian distribution that does not represent the signal in the full dataset.

Conclusions

- Particle method performance decreases with an increasing dimension of the observational space
- Information content of reduced InSAR data:
 - 1 **Point scatterers:** conserve the same amount of information but reduces the number of observations from 1.5 million to 600 000
 - 2 **Optimal length δl :** with an observation grid of 0.03 degrees (~ 3 km) we show that $\delta l < 2$ km represents the best the information content in the full dataset

Thank you
