Quantifying uncertainty with high quality probabilistic predictions of streamflow provides more realistic risk estimates

Probabilistic predictions provide realistic risk estimate (~5-10%) of high flow event

Deterministic predictions underestimate high flow event by 50%

How do we get high quality probabilistic predictions from deterministic predictions of existing hydrological models?

Challenge: Existing hydrological models are often pre-calibrated using common objective functions

- Nash-Sutcliffe Efficiency (NSE), Kling-Gupta Efficiency (KGE) and others

Common objective functions have assumptions that are inconsistent with actual residuals

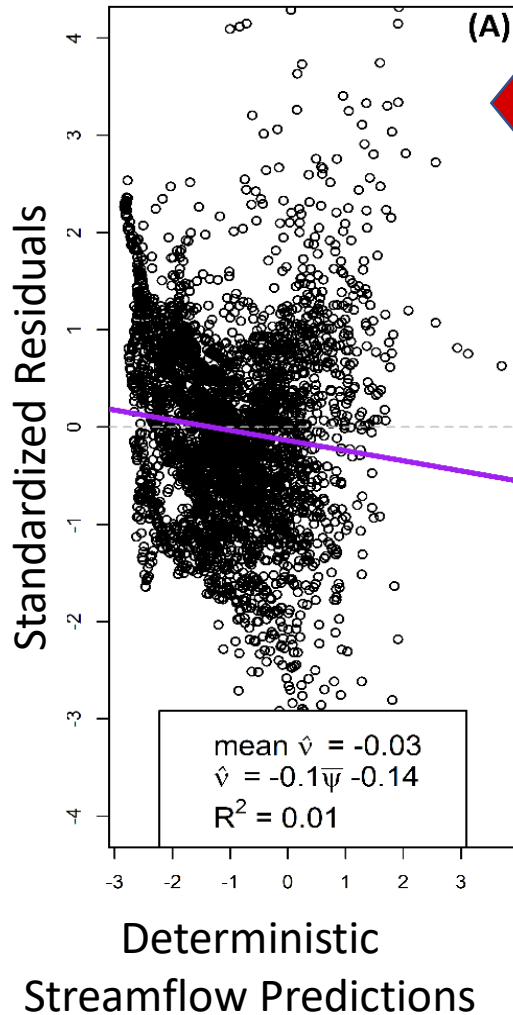

- Nash-Sutcliffe Efficiency (NSE)
=> assumes residuals are normally distributed: homoscedastic, no skew
- Actual Residuals
=> heteroscedastic/skewed/persistence
- Same applies to range of other common objective functions (KGE, NSE+BIAS)

How do we get high quality probabilistic predictions from deterministic predictions using objective functions that have “inconsistent” assumptions?

Impact of Objective Function on Residuals

“Consistent”
Objective Function

Consistent assumptions
 \Rightarrow no flow dependence in
residuals (zero mean)

Inconsistent assumptions
 \Rightarrow Linear trend in residuals

Suggest flow-dependent mean in
residuals could help overcome
inconsistency

“Inconsistent”
Objective Function

Incorporating flow dependent mean provides more reliable and precise probabilistic predictions

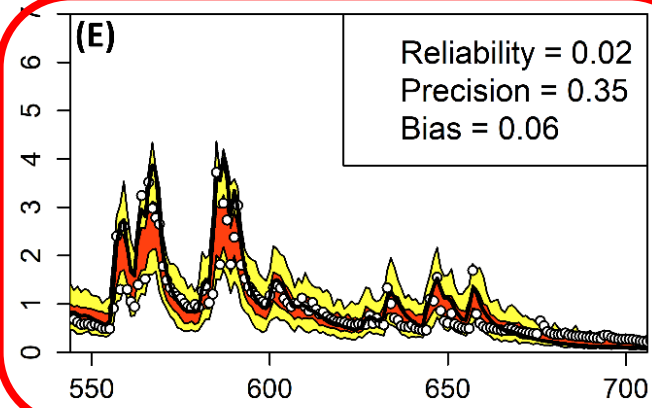

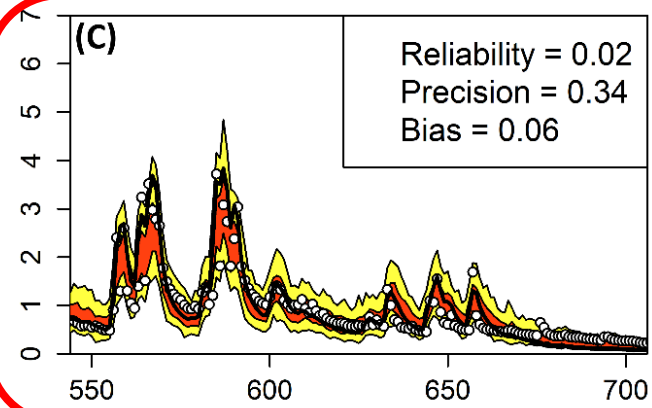

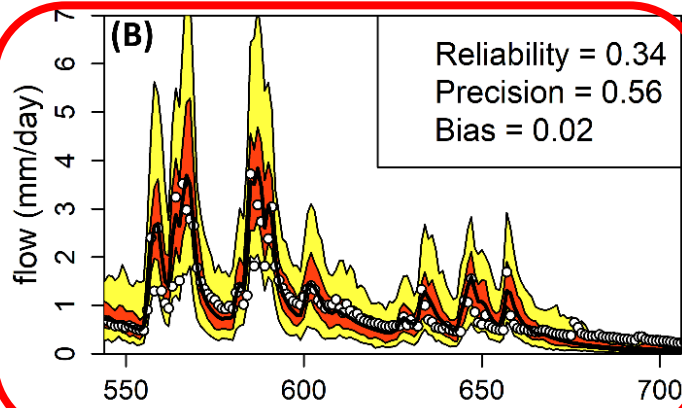

Lower is better for all metrics

Objective Function:
Nash-Sutcliffe Efficiency

Objective Function:
Kling Gupta Efficiency

Zero Mean

Flow Dependent Mean

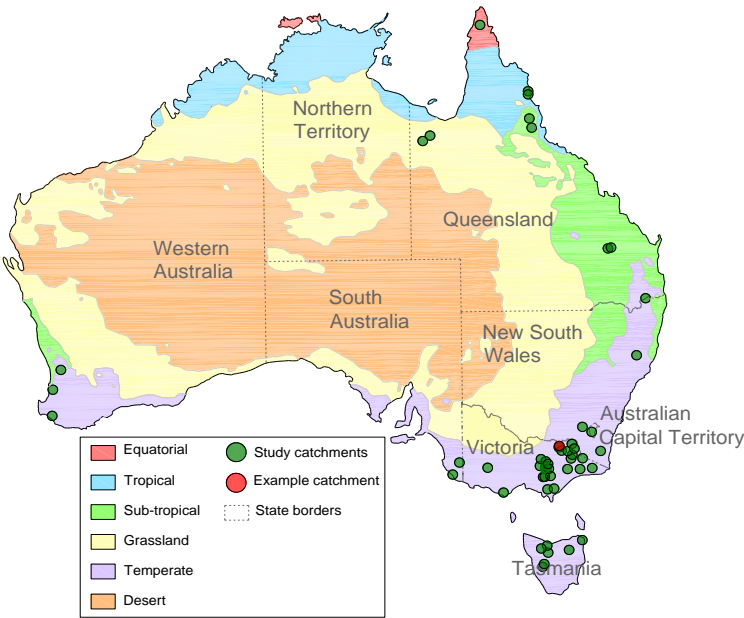

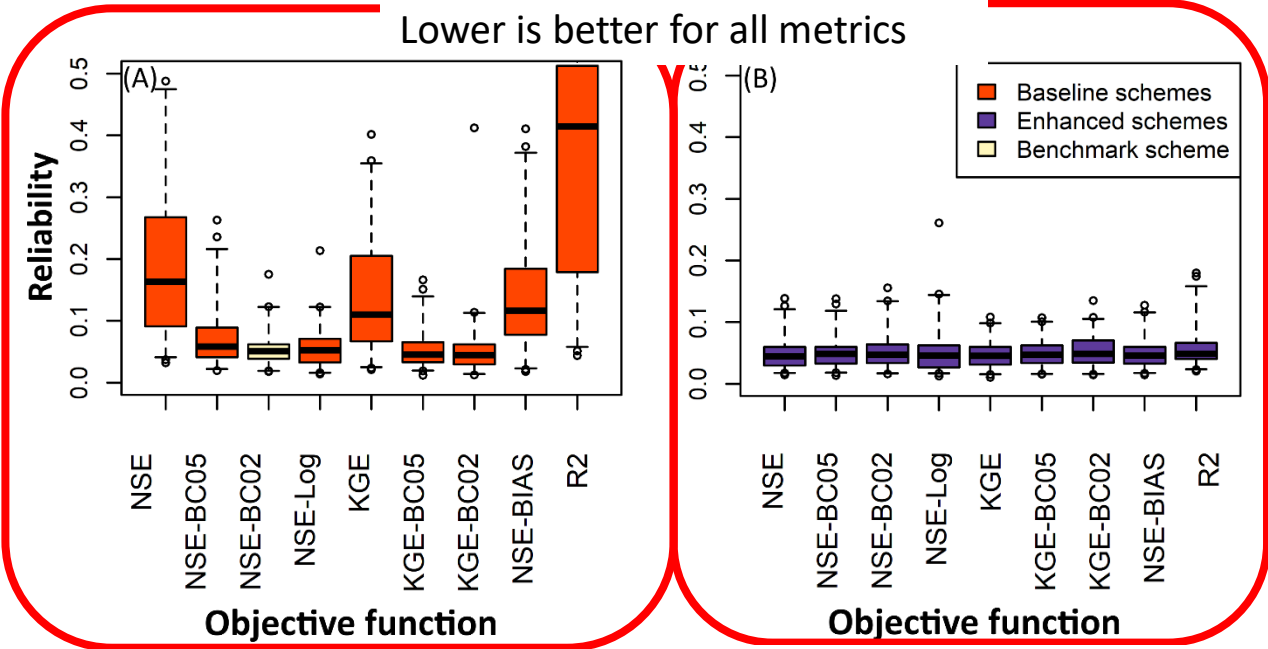

○ Observed streamflow
— Deterministic predictions
■ 50% probability
■ 90% probability

Flow dependent mean achieves high quality probabilistic predictions for wide range of objective functions & catchments

Zero Mean

Flow Dependent Mean

High quality probabilistic predictions are now easily achievable
